Neural networks have emerged as powerful and versatile tools in the field of deep learning. As the complexity of the task increases, so do size and architectural complexity of the network, causing compression techniques to become a focus of current research. Parameter truncation can provide a significant reduction in memory and computational complexity. Originating from a model order reduction framework we apply the Discrete Empirical Interpolation Method to the gradient descent training of neural networks and analyze for important parameters. We compare our approach for various state-of-the-art neural networks to established truncation methods. Further metrics like $L_2$ and Cross-Entropy Loss, as well as accuracy and compression rate are reported.

1 Preliminaries

In this paper we want to investigate the approximation of the neural network evaluation by a reduced network, where the truncation is obtained by applying the index selection process of the discrete empirical interpolation method (DEIM), known from the field of model order reduction (MOR). DEIM is a hyper reduction technique used to interpolate nonlinear functions, which accelerates repeated evaluations. This paper is structured as follows. Section 1.1 provides an introduction to projection based MOR via the proper orthogonal decomposition (POD) method. Section 1.2 introduces the DEIM approach. Section 2 provides a brief description of neural network truncation, also known as pruning, and describes the application of DEIM in this context. We provide a numerical example and our conclusions in Sections 3 and 4.

1.1 Projection based model order reduction

Partial differential equations (PDEs) arise in various fields of natural sciences and engineering. Since analytic solutions of general partial differential equations can only be obtained in a small number of special cases, numerical methods for computing an approximation to the exact solution have been developed. Generally, the state space $\Omega$ is discretized using methods like finite elements or finite volumes into a finite subset $\{x_1, \ldots, x_n\} = \Omega_n \subset \Omega$. For exemplary purposes, let $\Omega$ be the spatial domain on which the dynamics are defined and $f$ the nonlinearity in the PDE

\[
\begin{align*}
\frac{\partial u}{\partial t} &= \mathcal{L}u + f(u) \quad \text{in } (0,T) \times \Omega, \\
u(t,x) &= 0 \quad \text{for } (t,x) \in (0,T) \times \partial \Omega, \\
u(0,x) &= u_0(x) \quad \text{for } x \in \Omega
\end{align*}
\]

with Dirichlet boundary conditions. Utilizing for example the finite differences discretization scheme, one obtains a system of ordinary differential equations (ODEs)

\[
\dot{y} = Ay + F(y), \quad y(0) = y_0 = (u_0(x_1), \ldots, u_0(x_n))^T,
\]

where $A \in \mathbb{R}^{n \times n}$ is a constant matrix corresponding to the spatial discretization of the differential operator $\mathcal{L}$ and

\[
F : \mathbb{R}^n \rightarrow \mathbb{R}^n, y \mapsto F(y) := (f(y_1), \ldots, f(y_n))^T
\]

is a (nonlinear) function defined by the componentwise evaluation of $f$. The dimension of system (2) is determined by the number of discretization points $n$, which is growing exponentially in the dimension of $\Omega$. In order to numerically solve PDE (1) the system of ODEs (2) is evolved in time. The approximate solution of the original system is then given by $u(t, x_i) \approx y_i(t), \ i = 1, \ldots, n$. Clearly, for high spatial resolutions the dimension $n$ of the discretized systems can become very large, which results in expensive computations and high memory complexity. If in addition a fine time resolution is needed and the evolution equation has to be solved multiple times, e.g. for various parameters or initial conditions, computational costs might become unreasonably high. To resolve this issue MOR techniques have been developed, see for example [1–4]. Here, we introduce POD and DEIM.

∗ Corresponding author: e-mail jan.martin.nicolaus@uni-potsdam.de
In the POD framework one seeks to find a set of orthonormal basis vectors \( \{v_1, \ldots, v_r\} \subset \mathbb{R}^n \), with \( r \ll n \), such that the true system state \( y(t) \) can be approximated in the “trial subspace” \( V_r = \text{span}\{v_1, \ldots, v_r\} \), i.e.

\[
y(t) \approx V_r y_r(t),
\]

for some coefficient vector \( y_r(t) \in \mathbb{R}^m \) and \( V_r = [v_1, \ldots, v_r] \in \mathbb{R}^{n \times r} \). By substituting the approximation of \( y \) into equation (2) one obtains the approximation

\[
V_r y_r \approx AV_r y_r + F(V_r y_r).
\]

To restore equality, the residual \( V_r y_r - AV_r y_r - F(V_r y_r) \) is “tested” against an \( r \) dimensional “test subspace” \( W_r \subset \mathbb{R}^n \).

In more detail, the Petrov-Galerkin conditions

\[
W_r^T (V_r y_r - AV_r y_r - F(V_r y_r)) = 0, \quad W_r = [w_1, \ldots, w_r] \in \mathbb{R}^{n \times r}
\]

are enforced, where the subspace \( W_r \) is spanned by the orthonormal columns of \( W_r \). From the Petrov-Galerkin conditions (5) we obtain

\[
W_r^T V_r y_r = W_r^T A V_r y_r + W_r^T F(V_r y_r) \quad \text{or} \quad E_r y_r = A_r y_r + W_r^T F(V_r y_r)
\]

by redefining \( E_r := W_r^T V_r \in \mathbb{R}^{r \times r} \) and \( A_r := W_r^T A V_r \in \mathbb{R}^{r \times r} \). The resulting reduced order model (ROM) (6) is a system consisting of \( r \ll n \) variables and equations. If the \( r \) is sufficiently small compared to the dimension \( n \) of the full order model (FOM), the time required to obtain an approximation of the PDE solution (1) can be reduced significantly. Often it is convenient to choose the Galerkin projection \( W_r = V_r \), which leads to \( E_r = I_r \).

While it is possible to project the linear system dynamics onto a smaller subspace using POD, the nonlinear part of equation (6) remains to be evaluated on \( n \) components. Since \( F \) might not be explicitly known, precomputing \( W_r^T F(V_r \cdot) \) is likely not possible. The reduction given by POD can therefore generally not accelerate the computation of the costly nonlinear term. Utilising DEIM [5], introduced in the next section, it suffices to compute \( F \) on only \( k \ll n \) inputs and interpolate the output of the remaining components.

1.2 The Discrete Empirical Interpolation Method

As stated previously, the nonlinear function \( W_r^T F(V_r \cdot) \) of the projected system dynamics (6) is generally not precomputable. Due to the structure of the nonlinear function \( F \), given by the componentwise evaluation of \( f \), cf. (3), the computational complexity of an evaluation of \( F \) is \( O(n \alpha) \), where \( \alpha \) is the complexity of a single evaluation of \( f \). Reducing the complexity of \( F \) therefore corresponds to either decreasing the number of components \( f \) is evaluated at or decreasing \( \alpha \). DEIM [5] finds a set of \( k \ll n \) indices \( \{i_1, \ldots, i_k\} \subset \{1, \ldots, n\} \) and constructs a linear interpolation of the form

\[
F(y) = \begin{bmatrix} f(y_{i_1}) \\ \vdots \\ f(y_{i_k}) \end{bmatrix} \approx \begin{bmatrix} f(y_{i_1}) \\ \vdots \\ f(y_{i_k}) \end{bmatrix} Q.
\]

For ease of notation we will denote the simultaneous evaluation of the nonlinear function \( f \) on the components index by \( \{i_1, \ldots, i_k\} \) with \( F([y_{i_1}, \ldots, y_{i_k}]) = [f(y_{i_1}), \ldots, f(y_{i_k})]^T \). Defining \( P \in \mathbb{R}^{n \times k} \) as a row selection matrix, s.t. \( P^T y = [y_{i_1}, \ldots, y_{i_k}]^T \), the linear interpolation of \( F(y) \) can be written as

\[
F(y) \approx Q F(P^T y).
\]

Here \( Q \in \mathbb{R}^{n \times k} \) is the interpolation matrix corresponding index selection \( \{i_1, \ldots, i_k\} \). Consequently, the costly function \( f \) only has to be evaluated at \( k \ll n \) components in each time step. Combined with the complexity of the matrix-vector multiplication of the linear interpolation one obtains \( O(nk + k \alpha) \) as computational complexity.

In more detail, the DEIM approach approximates the image space \( \text{Im}(F) \subset \mathbb{R}^n \) by a linear subspace \( U_k \subset \mathbb{R}^n \) with dimension \( \dim(U_k) = k \ll n \). If \( U_k \) is spanned by orthonormal vectors \( \{u_1, \ldots, u_k\} \) the evaluation of \( F(y) \) can be approximated by a linear combination of these basis vectors

\[
F(y) \approx U_k c(y),
\]

where \( U_k = [u_1, \ldots, u_k] \in \mathbb{R}^{n \times k} \). The coefficients \( c(y) \in \mathbb{R}^k \) can be uniquely determined by selecting \( k \) rows in the following way. The index subset \( \{i_1, \ldots, i_k\} \) is iteratively constructed by selecting the index \( i_j \) in the \( j \)-th iteration where the interpolation error of the basis vector \( u_j \) is maximal. The selection of the interpolation components \( P^T y \) of \( y \) in (7) is achieved.
by collecting standard basis vectors \( e_i \in \mathbb{R}^n \) into a matrix \( P = [e_{i_1}, \ldots, e_{i_k}] \in \mathbb{R}^{n \times k} \), which allows to require exactness in (8), e.g.

\[
P^T F(y) = P^T U_k c(y).
\]

Since \( P^T U_k \) is invertible, the unique solution is given by \( c(y) = (P^T U_k)^{-1} P^T F(y) \), resulting in

\[
F(y) \approx U_k (P^T U_k)^{-1} P^T F(y).
\]

Defining \( Q = U_k (P^T U_k)^{-1} \) and utilising the componentwise structure of \( F \), approximation (7) is obtained.

The advantage of utilizing DEIM in conjunction with POD, is that no additional computations required, if the subspaces \( V_r \) and \( U_k \) are constructed in the following way. First, singular value decompositions (SVD) of the snapshot matrices

\[
X := \{y(t_1), \ldots, y(t_s)\} = \mathbb{V}_X S_X \mathbb{W}_X^T \quad \text{and} \quad F := \{F(y(t_1)), \ldots, F(y(t_s))\} = \mathbb{V}_F S_F \mathbb{W}_F^T
\]

of the system state and the evaluation of \( F \) at observation times \( t_1, \ldots, t_s \) are computed. Let \( l_1, l_2 \) be the ranks of \( X \) and \( F \), respectively, then the matrices of left singular vectors are given by the orthonormal columns of the matrices \( \mathbb{V}_X = [v_1, \ldots, v_{l_1}] \in \mathbb{R}^{n \times l_1} \) and \( \mathbb{V}_F = [v_1, \ldots, v_{l_2}] \in \mathbb{R}^{n \times l_2} \). The right singular vectors form the orthonormal columns of the matrices \( \mathbb{W}_X \in \mathbb{R}^{l_1 \times l_1} \) and \( \mathbb{W}_F \in \mathbb{R}^{l_2 \times l_2} \). The singular values are contained in the diagonal matrices \( S_X = \text{diag}(\sigma_{X,1}, \ldots, \sigma_{X,l_1}) \) and \( S_F = \text{diag}(\sigma_{F,1}, \ldots, \sigma_{F,l_2}) \) in decreasing order. The projection matrices \( V_r \) and \( U_k \) are then constructed by taking the \( r \) and \( k \) leading singular vectors \( V_r = [v_{k_1}, \ldots, v_{k_r}] \) and \( U_k = [v_{l_1}, \ldots, v_{l_k}] \). The neglected singular values can be used to bound the error of the interpolation by the DEIM Algorithm.

## 2 Neural network pruning

Neural networks are a powerful class of models used in a wide range of applications, e.g. classification tasks, pattern recognition, simulation or surrogate modelling. Since these models often require a high number of parameters for complex tasks and therefore large amounts of computational power and memory, various approaches have been developed to address the computational challenges. These so called “Pruning” methods aim to remove parameters or even entire structures, e.g. filters in a convolutional layer, while trying to preserve the overall quality of predictions.

Training a neural network consists of finding sets of weights \( W \) and biases \( b \), such that a given Loss function \( L(W, b) \), for example the following \( L_2 \) Loss

\[
L(W, b) := \sum_{(x,y) \in (X \times Y)} \| N(x, W, b) - y \|_2^2,
\]

based on the Euclidean norm \( \| \cdot \|_2 \) is minimized, where \( N(x, W, b) \) is used to indicate the evaluation of the described neural network architecture with weights \( W \) and biases \( b \) on the input data \( x \in X \), the target output data is denoted by \( y \in Y \). Originating in the setting of optimization, the gradient descent method serves as the basis for more sophisticated optimization algorithms, like BFGS or the Adam optimizer. Given a set of parameters \( p^{(n)} = \text{vec}(W^{(n)}, b^{(n)}) \in \mathbb{R}^{np} \) at the \( n \)-th gradient descent training step, an update is performed according to

\[
p^{(n+1)} = p^{(n)} - \eta \nabla_p L(p^{(n)}),
\]

where \( \eta > 0 \) is called the learning rate. In the context of ODEs equation (9) can be regarded as an Euler discretization of the gradient flow

\[
\dot{p} = -\nabla_p L(p),
\]

with stepize \( \eta > 0 \). Generally, the gradient flow (10) does not contain an immediatly accessible linear component, causing the POD approximation (6)

\[
p_r = -W_r^T \nabla_p L(V_r p_r).
\]

not to be precomputable, which leads us to the use of the hyper reduction technique DEIM, described in Section 1.2. However, since the evaluation of a neural network \( N \) is inextricably linked to its structure, performing an intrusive truncation method like POD or DEIM is infeasible. If the objective is to obtain a ROM, that can be treated again as a neural algorithm.

Afterwards Algorithm 3, an extension of Algorithm 1, is performed. After the training of the randomly initialized network DEIM Algorithm is performed on each set of singular vectors, cf. equation (13) at the end of the previous section and [5].

In our numerical experiment a fully connect feedforward neural network with 4 layers, containing 20 neurons each with logistic sigmoid activation functions and four output neurons, is investigated. The total number of network parameters is hence \( n = 984 \). The network was trained on the simple classification task to assign the label \( e_i \in \mathbb{R}^4 \) to the point \((x_1, x_2)\) if \((x_1, x_2) \in M_i \). The network was trained using gradient descent over \( s = 10^4 \) epochs a training set consisting of 100 randomly chosen datapoints and the standard \( L_2 \) Loss. To construct the snapshot matrix \( F \) from equation (13), all gradients \( F(\tilde{p}^{(i)}) = -\nabla_p L(\tilde{p}^{(i)}), \quad i = 1, \ldots, s \) were collected during the training. To allow a better exploration of the image space of \( F \), \( n_s 400 \) additional gradients from \( n_s \) short training trajectories, each consisting of \( s_a \) gradient descend steps, were included.

The snapshot matrix \( F \) as constructed by Algorithm 2, therefore consists of \( n_p \) rows and \( s + n_s s_a \) columns. We compare our approach for \( n_s \in \{0, 10, 100\} \) and \( s_a = 10 \) to the baseline methods mentioned in the previous section, cf. eq. (11). The experiment is set up as follows. First, Algorithm 2 is performed with \( n_s = 100 \), returning the nonlinear snapshot matrix \( F_{100} \). From \( F_{100} \) the submatrices \( F_0 \) and \( F_{10} \), consisting of the first \( s \) and \( s + 10s_a \) columns are extracted. These submatrices correspond to the choice \( n_a = 0 \) and \( n_a = 10 \), respectively. For each matrix \( F_0, F_{10} \) and \( F_{100} \) the first \( n_y \) left singular vectors are computed. Subsequently the index selection process of the DEIM Algorithm is performed on each set of singular vectors, cf. equation (13) at the end of the previous section and [5]. Afterwards Algorithm 3, an extension of Algorithm 1, is performed. After the training of the randomly initialized network has converged, each pruning method is performed according to the second part of Algorithm 1. For each pruning method the
L2 Loss, Top1 accuracy, i.e. the ratio of correct predictions to total number of predictions, are reported. In addition we report the Cross-Entropy Loss $\sum_{i=1}^{100} y_i^T \log(q_i)$, where $\log(q_i)$ is the componentwise natural logarithm of $q_i$, which is the softmax rescaled output $N(x_i, W, b)$ and $y_i$ is the label corresponding to $x_i$. The metrics are computed at the percentages of remaining network parameters $c \in \{1, \frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \frac{1}{16}, \frac{1}{32}, \frac{1}{64}\}$. The experiment is repeated $K = 128$ times. To obtain the plots in Figure 2, the sample mean and sample standard deviation are computed for each pruning method and each compression rate.

4 Conclusions and further research

We would like to point out, that the index ordering $\{i_1, \ldots, i_n\}$ is fixed before Algorithm 3 is performed and does not depend on the weights of the neural network at the time of pruning. Therefore, in contrast to the pruning methods used for comparison, our approach does not adapt to the state of the neural network during the pruning procedure.

An immediate observation in Figure 2a is that the decay of singular values of $F_0$ is shifted by a slower initial decay, when additional trajectories ($n_a = 10, 100$) are incorporated into the snapshot matrix. In the case, where no additional trajectories were incorporated ($n_a = 0$), our approach outperforms MP for low compression rates $c = 1, \frac{1}{2}, \frac{1}{4}, \frac{1}{8}$ and is comparable to GMP for $c = 1, \frac{1}{2}, \frac{1}{4}$ in the Top1 accuracy metric with overall similar standard deviations compared to the reference methods, except random pruning. The reference method GMP outperforms all other methods for $c \geq \frac{1}{16}$. Our approach decreases over all metrics for $c \geq \frac{1}{16}$, when using additional trajectories in the snapshot matrices ($n_a = 10, 100$). In the case of high compression rates $c = \frac{1}{32}, \frac{1}{64}$, the pruning order derived from $F_{10}$ and $F_{100}$ show better scores over all metrics. Furthermore we observe a reduced standard deviation for our approach compared to the reference methods GMP and MP by up to one order of magnitude.

The results of the reported experiments, combined with the non-adaptivity of our approach to the network state during the pruning stage, suggest that an identification of an approximating sub network from the networks gradients is possible. Since we only conducted our experiments for a neural network of simple structure, further research, investigating the proposed approach for more complex structures, is needed. The decrease of standard deviation and overall comparable or better performance for $n_a = 100$ and $c = \frac{1}{32}, \frac{1}{64}$ suggest the existence and identification of an “essential” or “worst-case” subnetwork. A possible connection to the pathway decomposition of the neural tangent kernel, proposed in [7] is of interest. In addition, the view of residual neural networks in the context of dynamical systems [9] might allow an application of other MOR techniques.

Algorithm 2 Construction of nonlinear snapshot matrix $F$

```plaintext
$p ←$ initialize network with random weights
$F ← [ ]$

for $i = 1 : s$
do
  compute $F'(p) = -\nabla_p L(p)$
  $F ← [F, F'(p)]$
  $p ← p + F(p)$
end for

for $i = 1 : n_a$
do
  $p ←$ initialize network with random weights
  for $j = 1 : s_a$
do
    compute $F(p) = -\nabla_p L(p)$
    $F ← [F, F'(p)]$
    $p ← p + F(p)$
  end for
end for
```

Algorithm 3 Pruning experiment

```plaintext
for $j = 1 : K$
do
  $p ←$ initialize network with random weights
  $p ←$ train network until convergence criterion is reached
  for method in PruningMethods do
    $\hat{p} ← p$
    for $i = 1 : \text{NumPruningIterations}$
do
      $s(\hat{p}) ←$ score $\hat{p}$
      $M ←$ construct mask from $s(\hat{p})$
      $\hat{p} ←$ fine tune $p \odot M$
      compute metrics for specified compression rates
  end for
  end for

compute empiric mean and empiric standard deviation for each metric and compression rate
```
